1 Introduction

Functional Data Analysis (FDA), which has its roots in the work of Ulf Grenander and Kari Karhunen, is gaining more attention as researchers from different fields collect data that is functional in nature. Although classical statistical methods can often process this data, FDA has advantages in that it allows extracting information given by properties such as the smoothness of the underlying process or its derivatives (cf. Levitin et al. 2007). As Kokoszka and Reimherr 2017 describe, using methods from FDA should be considered when one variable of a given data set can be seen as smooth curves or functions. Therefore, data sets in FDA can include both realizations of scalar random variables and realizations of random functions. Examples of such curves are the absorption curves of light in the Near-infrared (NIR) spectrum by chemical samples.¹

This paper introduces Functional Linear Regression in a scalar-on-function setting. The distinct feature of this framework is that the regressor is a function, which makes a different approach to estimation necessary because the problem of estimating an unknown coefficient function is inherently infinite-dimensional. We then introduce two distinct ways of translating this infinite-dimensional problem into a finite-dimensional problem that can be addressed using theory from multivariate regression. First, a so-called basis expansion of the coefficient function and second, functional principal component regression. Both of these methods are dependent on a parameter choice called a truncation parameter for a functional basis and this paper focuses on exploring the selection of these parameters using cross validation.

In Section 2, we introduce the necessary theoretical concepts, describe the estimation procedures and address the theoretical importance of the truncation parameter. Section 3 contains a description of structure and results of our Monte-Carlo Simulation which is aimed at choosing an appropriate functional basis and truncation parameter for the aforementioned methods. The application in Section 4 then uses the insights from theory and simulation to choose an appropriate basis for the estimation of Octane values of gasoline samples based on Near-Infrared absorption curves. In Section 5 we give an outlook on possible extensions for this paper and describe limitations of our approach.

2 Theory

To allow for scalar-on-function regression, it is necessary to extend some concepts from multivariate regression to the realm of infinite-dimensional objects, as the statistics derived from infinite-dimensional random functions cannot be defined on a finite-dimensional space. One integral concept that has to be defined is a random function as a special case of a random variable. Paraphrasing a definition by Bauer 2020, a random variable $X : \Omega \rightarrow \Omega'$ is an \mathcal{A} - \mathcal{A}' -measurable function, where (Ω, \mathcal{A}, P) is a probability space and (Ω', \mathcal{A}') is a measure space. The typical case for a random variable realizing in \mathbb{R} is $(\Omega', \mathcal{A}') = (\mathbb{R}, \mathcal{B})$, where \mathcal{B} is the canonical σ -algebra on the real numbers. As a first intuition for the concept of a random function, it is possible to imagine a similar concept where a random variable does not realize as an element of the real numbers but as a function in a function space. A formalization of this idea makes some more in-depth considerations necessary. The following theoretical introduction closely follows chapters 2.3 and 2.4 from Hsing and Eubank 2015 and chapters 4.4 and 4.6 from Kokoszka and Reimherr 2017.

¹For more details on Near-Infrared-Spectroscopy, refer to the section on Near-Infrared-Spectroscopy in the Appendix.

2.1 Inner Products and Hilbert Spaces

In the following we restrict our analysis to vector spaces over \mathbb{R} but more a general formalization including other fields is possible. Let \mathbb{V} be a vector space over \mathbb{R} . Then, a function $\langle \cdot, \cdot \rangle : \mathbb{V} \times \mathbb{V} \rightarrow \mathbb{R}$ is called an inner product, if $\forall v, v_1, v_2 \in \mathbb{V}$ and $a_1, a_2 \in \mathbb{R}$ the following properties hold.

1. $\langle v, v \rangle \geq 0$
2. $\langle v, v \rangle = 0$ if $v = 0$
3. $\langle a_1 v_1 + a_2 v_2, v \rangle = a_1 \langle v_1, v \rangle + a_2 \langle v_2, v \rangle$
4. $\langle v_1, v_2 \rangle = \langle v_2, v_1 \rangle$

A vector space with an associated inner product is called an inner product space. [verbatim quote!] The inner product naturally defines a norm and an associated distance on the vector space.

$$\|v\| = \langle v, v \rangle^{\frac{1}{2}} \quad (1)$$

$$d(v_1, v_2) = \langle v_2 - v_1, v_2 - v_1 \rangle^{\frac{1}{2}} \quad (2)$$

If the inner product space is complete with respect to the induced distance, it is called a Hilbert space, denoted \mathbb{H} in the following. To extend the known concept of a basis in a finite dimensional space to the potentially infinite Hilbert spaces, it is necessary to define the closed span of a sequence of elements of \mathbb{H} . Recall that the span of a set of vectors $S \subseteq \mathbb{R}^P$ is given by

$$\text{span}(S) = \left\{ \sum_{i=1}^k \lambda_i v_i \mid k \in \mathbb{N}, v_i \in S, \lambda_i \in \mathbb{R} \right\} \quad (3)$$

The closed span $\overline{\text{span}}(S)$ of a sequence S in \mathbb{H} is defined as the closure of the span with respect to the distance induced by the norm. S is called a basis of \mathbb{H} if $\overline{\text{span}}(S) = \mathbb{H}$.

It is called an orthonormal basis if, in addition, the following properties hold.

1. $\langle v_i, v_j \rangle = 0 \quad \forall v_i, v_j \in S \quad i \neq j$
2. $\|v\| = 1 \quad \forall v \in S$

As in the case of a Banach space, each element of a Hilbert space can be expressed in terms of a corresponding basis. This can be done using a Fourier expansion of an element $x \in \mathbb{H}$ w.r.t. a basis $S = \{s_n\}$ as follows.

$$x = \sum_{j=1}^{\infty} \langle x, s_j \rangle s_j \quad (4)$$

As can be seen, differing from the case of Banach spaces, these representations can be limits of series as previously hinted at by using the closed span of the basis. As using an infinite number of basis functions is infeasible in applied contexts, an intuitive way to approximate elements of a Hilbert space is to use a truncated series.

$$x \approx \sum_{j=1}^K \langle x, s_j \rangle s_j \quad (5)$$

2.2 Random Functions in the Hilbert Space of Square-Integrable Functions

In functional data analysis, one Hilbert space of particular importance is the space of square-integrable functions on $[0, 1]$ denoted $\mathbb{L}^2[0, 1]$. To define it, look first at the measure space given by $([0, 1], \mathcal{B}, \mu)$

where \mathcal{B} is the Borel σ -algebra on $[0, 1]$ and μ is the Lebesgue-measure. Then $\mathbb{L}^2[0, 1]$ is the collection of all measurable functions f on $[0, 1]$ that fulfill the following condition.

$$\|f\|_2 = \int_0^1 |f|^2 d\mu < \infty \quad (6)$$

This ensures that a random function has a finite second moment so that the variance and covariance functions can be defined. Its inner product is defined.

$$\langle f_1, f_2 \rangle = \int_0^1 f_1 f_2 d\mu. \quad (7)$$

$\mathbb{L}^2[0, 1]$ is the function space that is most often used for theoretical considerations in functional data analysis, but analogous constructions can be made for every closed interval of \mathbb{R} . A random function defined on $\mathbb{L}^2[0, 1]$ is a function $X : \Omega \rightarrow \mathbb{L}^2[0, 1]$ defined on a common probability space (Ω, \mathcal{A}, P) where Ω is a sample space with σ -algebra \mathcal{A} and a probability space P . The realized $X(\omega)(t)$ for every $t \in [0, 1]$ is called a sample curve for the process. The collection of such sample curves constitutes a functional data set.

2.3 Functional Data Sets

Consider the case of a data set containing observations x_i of a random function X , measured at discrete points $t_{i,j}$:

$$x_i(t_{i,j}) \in \mathbb{R}, \quad i = 1, \dots, N, \quad j = 1, \dots, J_i, \quad t_{i,j} \in [T_1, T_2] \quad (8)$$

Each curve $x_i(t)$ exists $\forall t \in [T_1, T_2]$, but is only observed at discrete measurement points. The measurement points can be different for each sample. However, this is not a primary interest of this paper, and, therefore, we consider the case where curves are observed at a shared set of measuring points. In principle, these measurements can be seen as a discretized approximation of a realization of a random function. It causes necessities to represent the functional data with respect to some expansion technique. One technique to make the functional data smooth, truncated basis expansion, is introduced in the following sections.

As in the finite-dimensional setting, the concept of identically distributed and independent data is important for many aspects of functional data analysis, such as, for example, many inferential procedures. One example could be a set of NIR absorption spectra of gasoline samples in which curves are observed at a shared set of wavelengths and each sample stemming from the same production can be seen as a realization of the same random process.

2.4 Representing a Function in terms of a Basis

As previously described, a basis of a Hilbert space can be used to express its elements using the corresponding Fourier expansion. Let therefore $\{\phi_i(t) \mid i \in \mathcal{I}\}$ be the basis used to express or approximate a realization $X(\omega_0) = x(t)$ of $X(\omega)$. Then the following equation shows how a basis can be used to express a function as a weighted sum of its elements.

$$x(t) = \sum_{j \in \mathcal{I}} a_j \phi_j(t) \quad (9)$$

One very important question in this context is how the coefficients a_j $j \in \mathcal{I}$ are derived given a function $x(t)$. For the purposes of this paper, this process will remain a blackbox, but detailed information on the derivation of these coefficients can be found in **ADD CITATION!!!** Three examples of bases often used to approximate elements of $\mathbb{L}^2[0, 1]$ in practice and in the later parts of this paper are explained in the following. Diagrams showing a number of basis functions from these bases are shown in Part 6.2 of the Appendix.

Monomial Basis For functions that fall into the class of entire functions, we can express the function as a potentially infinite sum of weighted monomials. Let $f(t)$ be an entire function, e.g. a polynomial, the exponential function or a trigonometric function, then we can write the following.

$$f(t) = \sum_{i=1}^{\infty} a_i t^i \quad \text{where} \quad a_i = \frac{f^{(i)}(0)}{i!} \quad (10)$$

But even for functions that do not fall into this category, like the logarithm, using a truncated Taylor expansion around a chosen point can often lead to reasonable approximations around this specific point or even on \mathbb{R} as a whole. From this idea, it is natural to use the monomials as a potential basis to approximate functions in $\mathbb{L}^2[0, 1]$. As in the case of the Taylor expansion, it is not necessary to approximate a function around zero as shown above, instead one can introduce a shift parameter. This shift parameter α is often chosen such that the monomials are evaluated at the center point of the domain of the function.

$$\phi_i^M(t) = (t - \alpha)^i, \quad i \in \mathcal{I} \quad (11)$$

Due to the chosen implementation for our simulation, we will limit our paper to the case of $\alpha = 0$. However, a different choice of α could lead to improvements in performance of the monomial basis in later parts of this paper. Collinearity problems arise since the monomials become more correlated to each other as their degree increases, which can result in numerically unstable calculations. This restricts the number of basis functions that can be used in the estimation procedures limiting its ability to capture pronounced local peculiarities. It can also lead to undesirable behavior away from the point of evaluation of the monomials (cf. Ramsay and Silverman 2005).

Fourier Basis In the same way the monomial basis is connected to the Taylor series, the Fourier basis corresponds to the Fourier series. The Fourier series can be used to decompose a periodic function into a weighted sum of trigonometric functions. Equation 12 shows an example for a periodic function with a period of 1.

$$s(x) = \frac{A_0}{2} + \sum_{i=1}^{\infty} A_n \cos(2\pi i x - \phi_n) = \frac{a_0}{2} + \sum_{i=1}^{\infty} [a_i \cos(2\pi i x) + b_i \sin(2\pi i x)] \quad (12)$$

In its classical form, the series is represented in the so called amplitude-phase form. This, however, is impractical for the estimation procedures shown in the later parts of this paper due to the phase shift. Therefore, rewriting the series in the sine-cosine form through a simple trigonometry formula as shown above is necessary. Due to this origin of the Fourier basis it is reasonable to restrict the number of Fourier basis functions to odd numbered values to stay true to the expansion in amplitude-phase form. The Fourier basis for $\mathbb{L}^2[0, 1]$ is thus given by the following sequence of functions defined on $[0, 1]$ directly corresponding to the terms of the sine-cosine form of the Fourier series.

$$\phi_i^F(x) = \begin{cases} 1 & \text{if } i = 1 \\ \sqrt{2} \cos(\pi i x) & \text{if } i \text{ is even} \\ \sqrt{2} \sin(\pi(i-1)x) & \text{otherwise} \end{cases} \quad (13)$$

Its elements exhibit a cyclical behavior which is useful to expand functions that represent a periodic or seasonal underlying process. Additionally, the Fourier basis is especially suitable to expand functions with a similar curvature order across the domain, generally resulting in uniformly smooth expansions.

Citation

B-spline Basis Following chapter 3.5 from Ramsay and Silverman 2005, splines are defined by first dividing an interval of interest $[\tau_0, \tau_L]$ into L subintervals of non-negative length divided by a non-decreasing sequence of points $(\tau_l)_{l=1, \dots, L-1}$ called knots. On each subinterval, a spline is a polynomial of chosen order $m = n + 1$ where n is its degree. If there are no multiplicities in the set of these knots, the polynomials on neighboring subintervals are matching derivatives up to order $m - 2$ at the boundary knot τ_l . A typical case of this that is often used in practice is an equidistant grid of knots. In some settings, however, it can be sensible to place multiple knots at the same value to replicate specific properties of the data structure allowing for a reduced number of matching derivatives at the corresponding knots. For the purposes of this paper, we will focus on the case of equidistant knots without multiplicity at inner knots.

B-splines are a specific system of spline functions developed by Boor 1978 and are defined by a recursive procedure. Let $\phi_{l,m}^{BS}(x)$ $l \in \{1, \dots, L-1\}$ be a B-spline of order m for an interval $[\tau_0, \tau_L]$ and inner knots $\{\tau_l \mid l = 1, \dots, L-1\}$, then it is defined by the Cox-de Boor recursion formula as follows.

$$\phi_{l,0}^{BS}(x) = \begin{cases} 1 & \text{if } x \in [\tau_l, \tau_{l+1}) \\ 0 & \text{otherwise} \end{cases} \quad (14)$$

$$\phi_{l,m}^{BS}(x) = \frac{x - \tau_l}{\tau_{l+m} - \tau_l} \phi_{l,m-1}^{BS}(x) + \frac{\tau_{l+m+1} - x}{\tau_{l+m+1} - \tau_{l+1}} \phi_{l+1,m-1}^{BS}(x)$$

As this equation references knots that are not defined by the original vector of knots, implementations of this algorithm typically repeat the knots at the boundaries of the interval, τ_0 and τ_L an additional m times. This padding of the knot vector then allows to calculate every object that is needed for the definition of the basis over the original set of knots.

This, however, does not really lead to a basis of $\mathbb{L}^2[0, 1]$ as the closed span of this finite sequence of functions is not equal to $\mathbb{L}^2[0, 1]$. To focus on specific approximation errors in the later parts of this paper, we will, however, assume that a B-spline basis representation of a function in $\mathbb{L}^2[0, 1]$ will serve as a sufficient approximation for an appropriately chosen number of B-spline basis functions. Even though, this approach is not theoretically exact, in practice, this is often a reasonable approach and yields satisfactory results in cases where the functional form of B-splines makes them an appropriate approximation tool.

As the B-spline basis does not have infinitely many elements as the full Monomial or Fourier bases do, it is slightly misleading to speak of truncating the B-spline basis at a truncation parameter L in later parts of this paper. For the sake of keeping the notation reasonably concise, we will still keep this notation. However, by convention, truncating a B-spline basis at truncation parameter L shall mean using a B-spline basis consisting of L functions from this point on.

2.5 Approximation and Smoothing via Basis Truncation

As mentioned above, the realized curves can be expressed in terms of a chosen functional basis. For this expansion, it is technically possible to use a complete basis of $\mathbb{L}^2[0, 1]$. In many cases this is not a desirable approach as the expansion with too many basis functions introduces high amounts of variance in pronounced local variations of the curves or can even led to the approximation of noise in the sample curves, which possibly interrupts the analysis. **Therefore, methods such as acceleration penalties have to be employed to smooth the function.** On the other hand, important information on the curves could be missed by using a number of basis functions that is too small. In that sense, this discussion is subject to the Bias-Variance tradeoff. It challenges the researcher to seek a point at which they truncate the basis function to remove noise and, at the same time, not to introduce too much bias by maintaining significant fluctuations of the curves. The basis expansion with truncation is given by Equation 15.

$$X(\omega_0) = x(t) = \sum_{j \in \mathcal{I}} A_j(\omega_0) \phi_j(t) = \sum_{j=1}^L A_j(\omega_0) \phi_j(t) + \delta(t) \approx \sum_{j=1}^L A_j(\omega_0) \phi_j(t) \quad (15)$$

where $\delta(t)$ is the truncation error and $L \leq \max_{j \in \mathcal{I}}(j)$ for all $L \in \mathcal{I}$. The number L can be chosen subjectively, but also through applying a data-driven method such as Cross-Validation. Figure 1 shows the effect of choosing different numbers of basis functions for one observation for the case of the Near-Infrared Spectroscopy dataset which is used in the later parts of this paper and exemplifies the tradeoffs that are at the core of the parameter choice.

Figure 1: B-spline Approximations of NIR Absorption Spectra with different Basis Truncation Parameters

2.6 Karhunen-Loève Expansion and Empirical Eigenbases

Given a realization of a random function $X : \Omega \mapsto \mathbb{L}^2[0, 1]$, it is possible to represent this realization in terms of its generating stochastic process. To do so, it is necessary to define the mean and covariance

functions of $X(\omega)$.

$$\mu(t) = \mathbb{E}[X(\omega)(t)] \quad (16)$$

$$c(t, s) = \mathbb{E}[(X(\omega)(t) - \mu(t))(X(\omega)(s) - \mu(s))] \quad (17)$$

where the $c(t, s)$ are Hilbert-Schmidt Kernels defined through $c : [0, 1] \times [0, 1] \rightarrow \mathbb{R}$. Let K be a Hilbert-Schmidt operator on $\mathbb{L}^2[0, 1]$ such that $K : \nu \rightarrow K\nu$ for $\nu \in \mathbb{L}^2[0, 1]$, by

$$[K\nu](t) = \int_0^1 c(t, s)\nu(s)ds = \lambda\nu(t) \quad (18)$$

More exact definitions are provided at 7.1. Then, the operator K has orthonormal basis functions $\nu^m \in \mathbb{L}^2[0, 1]$ corresponding to eigenvalues λ^m for all m since it is a positive compact self-adjoint operator (cf. Alexanderian 2015). Moreover, K holds that the eigenvalues can be ordered in nonincreasing order as follows $\lambda^1 \geq \lambda^2 \geq \dots \geq 0$ where the superscript is not the power but index. Therefore, the functions X are approximated enough well by first few principal components since the order of them are sorted in descending order of eigenvalues corresponding to the eigenfunctions (e.g. $Var(\xi^m) \geq Var(\xi^n)$ for all $m < n$). Theoretical considerations lead to the result that X can be represented in the following form, called its Karhunen-Loève expansion. The proofs are provided at 7.2 and 7.3.

$$X(\omega)(t) = \mu(t) + \sum_{m \in \mathbb{N}} \xi^m(\omega) \nu^m(t), \quad \xi^m(\omega) = \int_0^1 (X(\omega)(s) - \mu(s)) \nu^m(s) ds \quad (19)$$

where the ν^m are defined by the countable set of solutions $\{(\lambda^m, \nu^m) \mid m \in \mathbb{N}\}$ of (18). The random variables $\xi^m(\omega)$ satisfy following properties.

1. $\mathbb{E}[\xi^m(\omega)] = 0$
2. $Cov(\xi^m(\omega), \xi^n(\omega)) = 0$ if $m \neq n$
3. $Var(\xi^m(\omega)) = \lambda^m$

In the scalar setting, a similar consideration leads to the concept of principal components, which can be extended to the functional setting. Let $\{x_1(t), \dots, x_n(t)\}$ be a set of i.i.d. realizations generated by a random function $X(\omega) \mapsto \mathbb{L}^2[0, 1]$. Define the following sample analogs for the mean and covariance functions.

$$\hat{\mu}(t) = \frac{1}{N} \sum_{i=1}^N x_i(t) \quad (20)$$

$$\hat{c}(t, s) = \frac{1}{N} \sum_{i=1}^N (x_i(t) - \hat{\mu}(t))(x_i(s) - \hat{\mu}(s)) \quad (21)$$

With these it is possible to derive a set of sample analogs $\{(\hat{\lambda}^m, \hat{\nu}^m) \mid m = 1, \dots, N-1\}$ for $\{(\lambda^m, \nu^m) \mid m \in \mathbb{N}\}$ as the solutions of the following equation. As in the case of ordinary principal components, the number of eigenfunctions corresponding to non-zero eigenvalues is limited (cf. chapter 8.2.3 Ramsay and Silverman 2005). As each curve is infinite dimensional, there is no upper limit to this number due to the dimensionality. However the number of curves still imposes an upper limit of $N - 1$ non-zero eigenvalues, where N is the number of curves in the data set.

$$\int_0^1 \hat{c}(t, s) \hat{\nu}(s) ds = \hat{\lambda} \hat{\nu}(t) \quad (22)$$

This naturally leads to the following representation.

$$x_i(t) = \hat{\mu}(t) + \sum_{j=1}^{N-1} \hat{\xi}_i^m \hat{\nu}^m(t) \quad (23)$$

where the $\hat{\xi}_i^m$ are derived as

$$\hat{\xi}_i^m(\omega) = \langle x_i - \hat{\mu}, \hat{\nu}^m \rangle = \int_0^1 (x_i(s) - \hat{\mu}(s)) \hat{\nu}^m(s) ds \quad (24)$$

In reality, these calculations are often done using basis representations of both the functional principal components $\hat{\nu}^m$ and the observations $x_i(t)$ leading to the following representation. For the sake of clarity, the following equation assumes that the bases used for the expansion of both the observations and the coefficient function are true bases of $\mathbb{L}^2[0, 1]$ and can therefore be used to express the corresponding objects exactly.

$$\begin{aligned} \hat{\xi}_i^m &= \int_0^1 (x_i(s) - \hat{\mu}(s)) \hat{\nu}^m(s) ds = \int_0^1 \left(\sum_{j \in \mathcal{I}} a_{i,j} \phi_j(s) \right) \left(\sum_{k \in \mathcal{L}} b_k^m \psi_k(s) \right) ds \\ &= \int_0^1 \left(\sum_{j=1}^J a_{i,j} \phi_j(s) + \delta_i^J(s) \right) \left(\sum_{k=1}^K b_k^m \psi_k(s) + \delta_\beta^K(s) \right) ds \\ &= \sum_{j=1}^J \left[a_{i,j} \sum_{k=1}^K b_k^m \int_0^1 \phi_j(s) \psi_k(s) ds \right] + \sum_{k=1}^K b_k^m \int_0^1 \delta_i^J(s) \psi_k(s) ds + \sum_{j=1}^J a_{i,j} \int_0^1 \phi_j(s) \delta_\beta^K(s) ds \end{aligned} \quad (25)$$

In practice, a typical choice is to use the same basis $(\phi_j(t))_{j \in \mathcal{I}}$ and the same truncation parameter L for the basis expansion of the curves for both the demeaned observations $(x_i(t) - \hat{\mu}(t))$ and the functional principal components $\hat{\nu}^m$. This leads to the following simplification of Equation 25.

$$\hat{\xi}_i^m = \sum_{j=1}^L \left[a_{i,j} \sum_{k=1}^L b_k^m \int_0^1 \phi_j(s) \psi_k(s) ds \right] + \sum_{k=1}^L b_k^m \int_0^1 \delta_i^L(s) \psi_k(s) ds + \sum_{j=1}^L a_{i,j} \int_0^1 \phi_j(s) \delta_\beta^L(s) ds \quad (26)$$

And we can define the following objects:

$$\tilde{\xi}_i^{m,L} := \sum_{j=1}^L \left[a_{i,j} \sum_{k=1}^L b_k^m \int_0^1 \phi_j(s) \psi_k(s) ds \right] \quad \delta_{\xi,i}^L := \hat{\xi}_i^m - \tilde{\xi}_i^{m,L} \quad (27)$$

$$\tilde{\nu}^{m,L}(t) := \sum_{k=1}^L b_k^m \phi_k(t) \quad \delta_{\nu,m}^L(t) := \hat{\nu}^m(t) - \tilde{\nu}^{m,L}(t) \quad (28)$$

This method of deriving or approximating the eigenfunctions and scores from a data set is introduced in Ramsay and Silverman 2005 (chapter 8.4.2) and implemented in the R-package `fda`. The following considerations and results of the simulation study might therefore serve as information about the performance of this method in a scenario where a limited number of basis functions is provided to the

method.

2.7 Scalar-on-Function Regression

In the simple scalar setting, one of the most important tools in econometrics is linear regression. Its goal is twofold: to gain information about the dependency between variables, but also to allow for prediction. To motivate the jump from multivariate regression to scalar-on-function regression, assume first a data generating process as follows.

$$Y = X\beta + \epsilon \quad (29)$$

Here, Y is the vector of response variables, X is the matrix containing the corresponding regressors in its columns and $\beta = (\beta_0, \beta_1, \dots, \beta_p)'$ is the vector containing the unknown coefficients. In this finite dimensional setting one important question is how to estimate the unknown coefficients β . The most well known estimator in all of econometrics, the Ordinary Least Squares (OLS) estimator, fulfills this purpose under a set of assumptions.

$$\hat{\beta}_{OLS} = (X'X)^{-1}X'Y \quad (30)$$

The concept of linear regression can be extended to a setting of functional data, where a scalar response variable is assumed to be dependent of a functional regressor. Even though integrating over the product of an observation with the coefficient function is not the only functional that can be used to create a data generating process involving functional observations, it is the most typical as it naturally extends the intuition from multiple linear regression to the realm of infinite-dimensional objects. Therefore, we will always assume a data generating process as follows in this paper.

$$Y(\omega) = \alpha + \int_0^1 \beta(s)X(\omega)(s)ds + \epsilon(\omega) \quad (31)$$

Here, $\beta(t)$ is an unknown coefficient function. Similar to the finite-dimensional setting, an interesting question is how to estimate $\beta(t)$ given a data set containing realizations of a random function and associated scalar response variables. However, a simple extension of the OLS estimator to allow for infinite-dimensional objects is not possible. Therefore, other options have to be considered.

2.7.1 Estimation using Basis-Representation

The most common way to make this problem tractable is via a basis representation of $\beta(t)$. Therefore, let $\{b_i(t) \mid i \in \mathcal{I}\}$ be a basis of $\mathbb{L}^2[0, 1]$ and represent $\beta(t)$ in terms of this basis.

$$\beta(t) = \sum_{j \in \mathcal{I}} b_j \phi_j(t) \quad (32)$$

This enables us to write equation 31 with $\beta(t)$ represented in this way to obtain a formulation as a sum of scalar random variables $Z_j(\omega)$.

$$\begin{aligned}
Y(\omega) &= \alpha + \int_0^1 \beta(s) X(\omega)(s) ds + \epsilon(\omega) = \alpha + \int_0^1 \left[\left(\sum_{j \in \mathcal{I}} b_j \phi_j(s) \right) X(\omega)(s) \right] ds + \epsilon(\omega) \\
&= \alpha + \sum_{j \in \mathcal{I}} \left[b_j \int_0^1 X(\omega)(s) \phi_j(s) ds \right] + \epsilon(\omega) = \alpha + \sum_{j \in \mathcal{I}} b_j Z_j(\omega) + \epsilon(\omega)
\end{aligned} \tag{33}$$

This representation translates the original problem of regressing a scalar on a continuously observed function to a problem where a scalar is regressed on what is possibly a countably infinite sequence of regressors. Using a truncation of the basis at some parameter J can be used to make this problem tractable if we assume that the approximation error created by this truncation is small.

$$\begin{aligned}
Y(\omega) &= \alpha + \int_0^1 \left[\left(\sum_{j=1}^J b_j \phi_j(s) + \delta_\beta^J(s) \right) X(\omega)(s) \right] ds + \epsilon(\omega) \\
&= \alpha + \sum_{j=1}^J b_j \int_0^1 \phi_j(s) X(\omega)(s) ds + \int_0^1 \delta_\beta^J(s) X(\omega)(s) ds + \epsilon(\omega)
\end{aligned} \tag{34}$$

In practice it is common to not only express the coefficient function in terms of a basis but also the observations. Therefore two bases $((\phi_j(t))_{j \in \mathcal{I}})$ and $(\psi_k(t))_{k \in \mathcal{L}})$ and two corresponding truncation parameters (J and K) can be chosen. This leads to the following representation.

$$\begin{aligned}
Y(\omega) &= \alpha + \int_0^1 \beta(s) X(\omega)(s) ds + \epsilon(\omega) = \alpha + \int_0^1 \left[\left(\sum_{j \in \mathcal{I}} b_j \phi_j(s) \right) \left(\sum_{k \in \mathcal{L}} a_k(\omega) \psi_k(s) \right) \right] ds + \epsilon(\omega) \\
&= \alpha + \int_0^1 \left[\left(\sum_{j=1}^J b_j \phi_j(s) + \delta_\beta^J(s) \right) \left(\sum_{k=1}^K a_k(\omega) \psi_k(s) + \delta_X^K(\omega)(s) \right) \right] ds + \epsilon(\omega) \\
&= \alpha + \sum_{j=1}^J b_j \left[\sum_{k=1}^K a_k(\omega) \int_0^1 \phi_j(s) \psi_k(s) ds \right] + \sum_{j=1}^J b_j \int_0^1 \phi_j(s) \delta_X^K(\omega)(s) ds \\
&\quad + \sum_{k=1}^K a_k(\omega) \int_0^1 \delta_\beta^J(s) \phi_j(s) ds + \epsilon(\omega)
\end{aligned} \tag{35}$$

A typical choice in this scenario is to use the same functional basis $(\phi_j(t))_{j \in \mathcal{I}}$ and the same truncation parameter L for both the coefficient function and the approximation of the observations. Defining the following notation

$$\tilde{Z}_j(\omega) = \sum_{k=1}^L \left[a_k(\omega) \int_0^1 \phi_j(s) \phi_k(s) ds \right] \quad j = 1, \dots, L \tag{36}$$

This leads to a considerable simplification of Equation 2.7.1.

$$\begin{aligned}
Y(\omega) &= \alpha + \sum_{j=1}^J b_j \tilde{Z}_j(\omega) + \sum_{j=1}^J b_j \int_0^1 \phi_j(s) \delta_X^K(\omega)(s) ds + \sum_{k=1}^K a_k \int_0^1 \delta_\beta^J(s) \phi_j(s) ds + \epsilon(\omega) \\
&\approx \alpha + \sum_{j=1}^J b_j \tilde{Z}_j(\omega) + \epsilon(\omega)
\end{aligned} \tag{37}$$

A model in the form of Equation 37 naturally lends itself to be estimated using theory from multivariate linear regression. Define therefore the following objects

$$Y = \begin{pmatrix} y_1 \\ \vdots \\ y_n \end{pmatrix}, \quad Z = \begin{pmatrix} 1 & \tilde{Z}_{1,1} & \dots & \tilde{Z}_{1,J} \\ \vdots & \vdots & \ddots & \vdots \\ 1 & \tilde{Z}_{N,1} & \dots & \tilde{Z}_{N,J} \end{pmatrix} \tag{38}$$

Then an OLS estimator can be calculated in the usual way to obtain an estimate for the values of α and b_j and an estimate of the coefficient function can be derived accordingly.

$$b^L = (Z'Z)^{-1} Z'Y \in \mathbb{R}^{L+1} \quad \hat{\alpha} = b_1^L \quad \hat{\beta}^L(t) = \sum_{j=1}^J b_{j+1}^L \phi_j(t) \tag{39}$$

The performance of this estimation procedure depends in part on the quality of the approximation in Equation 37. Therefore, it is interesting to think about when the approximation error is small...

[Continue Here Jakob!!!](#)

2.7.2 Estimation using Functional Principal Components

Using the Karhunen-Loéve Expansion to represent $X(\omega)$, it is also possible to express the data generating process in a slightly different way.

$$\begin{aligned}
Y(\omega) &= \alpha + \int_0^1 \textcolor{red}{X}(\omega)(s) \beta(s) ds + \epsilon(\omega) = \alpha + \int_0^1 \left(\mu(s) + \sum_{m=1}^{\infty} \xi^m(\omega) \nu^m(s) \right) \beta(s) ds + \epsilon(\omega) \\
&= \alpha + \int_0^1 \mu(s) \beta(s) ds + \sum_{m=1}^{\infty} \xi^m(\omega) \int_0^1 \nu^m(s) \beta(s) ds + \epsilon(\omega) = \bar{\alpha} + \sum_{m=1}^{\infty} \xi^m(\omega) \beta^m + \epsilon(\omega)
\end{aligned} \tag{40}$$

As these theoretical Eigenfunctions and Eigenvalues are typically unknown, the corresponding equation in sample analogs is more interesting as a representation of an observation.

$$\begin{aligned}
y_i &= \alpha + \int_0^1 \textcolor{red}{x}_i(s) \beta(s) ds + \epsilon_i = \alpha + \int_0^1 \left(\hat{\mu}(s) + \sum_{m=1}^{N-1} \hat{\xi}_i^m \hat{\nu}^m(s) \right) \beta(s) ds + \epsilon_i \\
&= \alpha + \int_0^1 \hat{\mu}(s) \beta(s) ds + \sum_{m=1}^{N-1} \hat{\xi}_i^m \int_0^1 \hat{\nu}^m(s) \beta(s) ds + \epsilon_i = \bar{\alpha} + \sum_{m=1}^{N-1} \hat{\xi}_i^m \hat{\beta}^m + \epsilon_i
\end{aligned} \tag{41}$$

This, however, is a simplification for the purposes of real-world estimation as in most implementations, the coefficient function and the principal components are also expressed or derived in terms of a basis that can be chosen freely. Introducing both concepts one step at a time leads to the following

complication if we first introduce an expansion of the coefficient function.

$$\begin{aligned}
y_i &= \alpha + \int_0^1 \textcolor{red}{x}_i(\textcolor{blue}{s})\textcolor{blue}{\beta}(\textcolor{blue}{s})\text{d}s + \epsilon_i = \alpha + \int_0^1 \left(\hat{\mu}(s) + \sum_{m=1}^{N-1} \hat{\xi}_i^m \hat{\nu}^m(s) \right) \left(\sum_{j \in \mathcal{I}} b_j \phi_j(s) \right) \text{d}s + \epsilon_i \\
&= \alpha + \int_0^1 \left[\sum_{j \in \mathcal{I}} b_j \phi_j(s) \hat{\mu}(s) + \sum_{m=1}^{N-1} \left[\hat{\xi}_i^m \sum_{j \in \mathcal{I}} b_j \hat{\nu}^m(s) \phi_j(s) \right] \right] \text{d}s + \epsilon_i \\
&= \alpha + \sum_{j \in \mathcal{I}} b_j \int_0^1 \phi_j(s) \hat{\mu}(s) \text{d}s + \sum_{m=1}^{N-1} \left[\hat{\xi}_i^m \sum_{j \in \mathcal{I}} b_j \int_0^1 \hat{\nu}^m(s) \phi_j(s) \text{d}s \right] + \epsilon_i
\end{aligned} \tag{42}$$

Truncating the basis used for expansion of the coefficient function already introduces an approximation error.

$$\begin{aligned}
y_i &= \alpha + \int_0^1 \left(\hat{\mu}(s) + \sum_{m=1}^{N-1} \hat{\xi}_i^m \hat{\nu}^m(s) \right) \left(\sum_{j=1}^J b_j \phi_j(s) + \delta_\beta^J(s) \right) \text{d}s + \epsilon_i \\
&= \alpha + \sum_{j=1}^J b_j \int_0^1 \phi_j(s) \hat{\mu}(s) \text{d}s + \int_0^1 \delta_\beta^J(s) \hat{\mu}(s) \text{d}s + \sum_{m=1}^{N-1} \left[\hat{\xi}_i^m \sum_{j=1}^J b_j \int_0^1 \hat{\nu}^m(s) \phi_j(s) \text{d}s \right] \\
&\quad + \sum_{m=1}^{N-1} \left[\hat{\xi}_i^m \int_0^1 \hat{\nu}^m(s) \delta_\beta^J(s) \text{d}s \right] + \epsilon_i
\end{aligned} \tag{43}$$

If we additionally derive and approximate the principal components and corresponding scores using a truncated basis representation as in Equation 26 we obtain the following. To not complicate things more than necessary, the following equation assumes that the same basis $(\phi_j(t))_{j \in \mathcal{I}}$ was used in the derivation of the principal components and the expansion of the coefficient function. Additionally, the following approximation also truncates the basis for the expansion of the coefficient function at the same parameter L that was used for the approximation of the principal components and scores.

For convenience, define the following notation:

$$\tilde{\alpha}^L = \alpha + \sum_{j=1}^L b_j \int_0^1 \phi_j(s) \hat{\mu}(s) \text{d}s + \int_0^1 \delta_\beta^L(s) \hat{\mu}(s) \text{d}s \tag{44}$$

Then Equation 43 can be expressed as follows.

$$\begin{aligned}
y_i &= \tilde{\alpha}^L + \sum_{m=1}^{N-1} \left[\left(\tilde{\xi}_i^{m,L} + \delta_{\xi,i}^{m,L} \right) \sum_{j=1}^L b_j \int_0^1 \left(\tilde{\nu}^{m,L}(s) + \delta_{\nu,m}^L(s) \right) \phi_j(s) ds \right] + \epsilon_i \\
&= \tilde{\alpha}^L + \sum_{m=1}^{N-1} \left[\tilde{\xi}_i^{m,L} \sum_{j=1}^L b_j \int_0^1 \tilde{\nu}^{m,L}(s) \phi_j(s) ds \right] + \sum_{m=1}^{N-1} \left[\tilde{\xi}_i^{m,L} \sum_{j=1}^L b_j \int_0^1 \delta_{\nu,m}^L(s) \phi_j(s) ds \right] \\
&\quad + \sum_{m=1}^{N-1} \left[\delta_{\xi,i}^{m,L} \sum_{j=1}^L b_j \int_0^1 \tilde{\nu}^{m,L}(s) \phi_j(s) ds \right] + \sum_{m=1}^{N-1} \left[\delta_{\xi,i}^{m,L} \sum_{j=1}^L b_j \int_0^1 \delta_{\nu,m}^L(s) \phi_j(s) ds \right] + \epsilon_i \\
&\approx \tilde{\alpha}^L + \sum_{m=1}^{N-1} \left[\tilde{\xi}_i^{m,L} \sum_{j=1}^L b_j \int_0^1 \tilde{\nu}^{m,L}(s) \phi_j(s) ds \right] + \epsilon_i
\end{aligned} \tag{45}$$

The parameter M corresponds to the chosen number of principal components and therefore constitutes another choice in the approximation. **Write equation with limited number of principal components. Truncation parameter M instead of $N-1$**

As in the previous section, this equation again lends itself for estimation with OLS. Define the following objects:

$$Y = \begin{pmatrix} y_1 \\ \vdots \\ y_n \end{pmatrix}, \quad Z = \begin{pmatrix} 1 & \tilde{\xi}_1^{1,L} & \dots & \tilde{\xi}_1^{M,L} \\ \vdots & \vdots & \ddots & \vdots \\ 1 & \tilde{\xi}_N^{1,L} & \dots & \tilde{\xi}_N^{M,L} \end{pmatrix} \tag{46}$$

We can then derive the following estimators.

$$\tilde{b}^{L,M} = (Z'Z)^{-1} Z'Y \in \mathbb{R}^{M+1} \quad \hat{\alpha} = \tilde{b}_1^{L,M} \quad \hat{\beta}^{m,L} = \tilde{b}_{m+1}^{L,M} \tag{47}$$

As in the previous case, the performance of this estimation depends the quality of the approximation made during the derivation of this estimator. Therefore, it is interesting to think about when these errors are small... **Continue Here Jakob!!!**

3 Simulation Study

3.1 Motivation

In the simulation study, we deviate from the standard simulation setting. Instead of generating data from scratch, we use the gasoline data, which consists of 60 samples of Near-infrared (NIR) spectra measured by 2-nm from 900 to 1,700 nm, and a response variable, the octane rating. We chose this setup to improve the approach towards the application in which we predict the octane ratings from the gasoline dataset.

To exploit the regularity of the curves of the spectra, we introduced different basis functions in [Link](#) and demonstrated the importance of the truncation parameter K for the estimation in [Link](#). For the simulation study, we rely on the introduced estimation strategies with the introduced basis functions and focus on selecting the truncation parameter K as well as the number of FPC, which is as well affected by K , by ten-fold cross-validation using the prediction mean-squared error. While cross-validation is common for selecting K , the number of FPC in practice is often truncated after a specified amount of explained variability Kokoszka and Reimherr 2017, which might not be optimal since FPC with

smaller eigenvalues may have greater influence on the prediction (c.f Jolliffe 1982). This might apply to this simulation too since certain eigenfunctions could correspond to certain chemical combinations and overtones in the absorption bands of the spectrum that could have high predictive power, but explain only little variability [Link to NIR](#).

This setup is opposing to the often used penalized functional regression as described by Goldsmith et al. 2011 in which an explicit smoothness constraint λ is used to tune the smoothness of the estimator $\hat{\beta}(t)$ while setting the K sufficiently high. This would avoid the heavy computing of validating the best value for K , which we will conduct in the simulation. To provide intuition in this approach, let

$$PSSE_{\lambda}(\alpha, \beta) = \sum_{i=1}^N \left[Y_i - \alpha - \int_0^1 \beta(t) X_i(t) dt \right]^2 + \lambda \int [D^m \beta(t)]^2 dt \quad (48)$$

denote the penalized residual sum of squares as notated by Ramsay and Silverman 2005 for the derivative of order m . A typical choice is the second derivative as highly variable functions are expected to yield large second derivatives and therefore a larger penalty. The smoothing parameter λ is set to minimize the $PSSE_{\lambda}(\alpha, \beta)$, which can be archived by different criteria as shown in Thomas C.M. Lee 2003.

3.2 Generating Similar Curves

To avoid small sample problems, we generated 200 similar curves from the gasoline dataset, motivated by Karhunen-Loève Expansion. First, the initial curves are expressed in terms of a generated cubic B-spline basis which is created using 50 knots. In the R implementation of the fda package that is used, these 50 knots account for 52 basis functions (50+4-2). These smooth curves are then centered, before applying the Karhunen-Loève Expansion. It is assumed that the scores follow a normal distribution, so the new realizations for the scores are drawn from a multivariate normal distribution $\hat{\xi} = (\hat{\xi}_1, \dots, \hat{\xi}_M)' \sim \mathcal{N}(0_M, \text{diag}(\hat{\lambda}_1, \dots, \hat{\lambda}_M))$. Finally, we obtain the generated curves NIR_{sim}

$$\hat{X}(\omega)(t) = \hat{\mu}(t) + \sum_{m=1}^M \hat{\xi}^m(\omega) \tilde{\nu}^{m,L}(t) \quad (49)$$

where $\hat{X}(\omega)(t)$, $\hat{\mu}(t)$ and $\tilde{\nu}^{m,L}(t)$ are approximated as vectors in \mathbb{R}^{401} for $M = 30$ FPC's.

3.3 Simulation setup

The simulation study follows Reiss and Ogden 2007 as a guideline. Two different true coefficient functions, $f_1(t)$ and $f_2(t)$, are created that differ in their smoothness, to compare the introduced methods with differing true coefficient functions:

$$f_1(t) = 401 [2 \sin(0.5\pi t) + 4 \sin(1.5\pi t) + 5 \sin(2.5\pi t)] \quad (50)$$

$$f_2(t) = 401 \left[1.5 \exp\left(\frac{-0.5(t-0.3)^2}{0.02^2}\right) - 4 \exp\left(\frac{-0.5(t-0.45)^2}{0.015^2}\right) + 8 \exp\left(\frac{-0.5(t-0.6)^2}{0.02^2}\right) - \exp\left(\frac{-0.5(t-0.8)^2}{0.03^2}\right) \right] \quad (51)$$

Figure 2: $f_1(t)$, smooth function

Figure 3: $f_2(t)$, bumpy function

The bumpy function, $f_2(t)$, was generated by referring to Cardot 2002. The smooth function $f_1(t)$ follows Reiss and Ogden 2007 and its inner product $\langle NIR_{sim}, f_1 \rangle$ creates responses that are similar to the original octane numbers of the gasoline dataset.

Two different error-terms ϵ were created by first generating an *i.i.d.* standard normal error term and then multiplying it by two error variations σ_e . The error variations represent different signal-to-noise ratios to test the methods with low and high amounts of noise. They are created such that the squared multiple correlation coefficient $R^2 = \text{var}(\langle X, f \rangle) / (\text{var}(\langle X, f \rangle) + \sigma_e^2)$ is equal to 0.9 and 0.6. The two error terms are then used to generate two sets of responses for $f \in \{f_1(t), f_2(t)\}$

$$\begin{aligned} Y_{1,f} &= \langle NIR, f \rangle + Z \left[\frac{\text{var}(\langle NIR, f \rangle)}{0.9} - \text{var}(\langle NIR, f \rangle) \right] \\ Y_{2,f} &= \langle NIR, f \rangle + Z \left[\frac{\text{var}(\langle NIR, f \rangle)}{0.6} - \text{var}(\langle NIR, f \rangle) \right] \end{aligned} \quad (52)$$

where $Z \sim \mathcal{N}(0, 1)$. In total, we created four combinations for the simulations, using the two true coefficient functions and the two sets of responses. These four combinations are then used with a different number of monomial basis functions $\in \{1, 2, \dots, 6\}$, cubic B-spline basis-function $\{5, 6, \dots, 18\}$ and Fourier functions $\{1, 3, \dots, 25\}$ to predict the generated responses using the basis expansion approach and the FPCR approach. For the evaluation, we used the prediction MSE calculated by 10 fold cross-validation. To obtain valid out of sample properties for the FPCR, within each of the ten ten-fold cross-validation splits, we first calculate the first $nharm$ FPC's for $nharm \in \{2, 3, 4\}$ of the training set \mathcal{T} for each curve $i \in \{1, 2, \dots, 200\}$, which was smoothed with the respective basis function specification. The obtained eigenfunctions $\nu^{m, \mathcal{T}}$ are then used to estimate the scores of the holdout set \mathcal{H} , $\hat{\xi}_i^{m, \mathcal{H}}$ by the equation

$$\begin{aligned} \hat{\xi}_i^{m, \mathcal{H}} &\approx \int_0^1 (X_i^{\mathcal{H}}(s) - \hat{\mu}^{\mathcal{T}}(s)) \hat{\nu}^{m, \mathcal{T}}(s) ds = \int_0^1 \left(\sum_{j=1}^L a_{i,j}^{\mathcal{H}} \phi_j(s) \right) \left(\sum_{k=1}^L b_k^{m, \mathcal{T}} \phi_k(s) \right) ds \\ &\approx \sum_{j=1}^L \left[a_{i,j}^{\mathcal{H}} \sum_{k=1}^L b_k^{m, \mathcal{T}} \int_0^1 \phi_j(s) \phi_k(s) ds \right] \end{aligned} \quad (53)$$

with truncation parameter m .

The simulation was done with R (version...). In total, 5000 repetitions were done for each set of simulations.

3.4 Results

The discussed results and figures of $\hat{\beta}(t)$ for the simulation can be found in the appendix.

3.4.1 Basis Expansion Regression

The following results origin from the **Estimation using Basis-Representation**, in which we transform the observed functions to perform regression of a scalar on a countable sequence of regressors, which is then tractable with typical multivariate regression theory.

Monomial Basis Due to the in the number of basis functions increasing collinearity of these basis functions, simulations were conducted up until the sixth monomial basis, which already shows signs of numerical instability. This could be solved using orthogonal polynomials like Legendre polynomials, see Dattoli, Ricci, and Cesarano 2001. For reasons outlined in [Link chapter](#), they seem suited for f_1 . The monomial basis shows a better performance than B-splines for this coefficient function. A hypothesis for this could be that f_1 resembles an entire function, which can be well approximated with a power series. In case of f_2 , this basis shows the weakest performance out of all basis, which is visible in figure 9 and 10, where it seems like $\hat{\beta}$ is not changing in the amount of noise and shows exaggerated behaviour at the boundaries. For f_1 , the simulation selects 5(3) and for f_2 5(5) monomial basis functions for the high(low) signal-to-noise ratios. This weakness is especially pronounced in the setup f_2, Y_1 ; for the high noise setup, f_2, Y_2 this weakness is still visible, but less pronounced.

B-spline Basis Simulations with B-spline basis functions were possible from 5 to 18, since from 18 onwards the simulations were running into problems concerning [what happened here exactly?](#) The smooth function f_1 requires only 5(4) B-spline basis functions, for the high(low) signal-to-noise ratio to obtain the best fit for the B-spline basis, which performs the worst for f_1 . An explanation might be its exaggerated behaviour at the boundaries and the exaggeration of the peculiarities of f_1 (figure 7 and 8), which is especially pronounced for the higher noise responses. For f_2 , 11(6) B-spline basis functions are chosen for the high(low) signal-to-noise ratios. For f_2 , the B-spline basis functions outperform the monomial basis but come second to the Fourier basis. While the basis seems to recognize the peculiarities in f_2, Y_1 , it seems to struggle with it for the noisy responses in f_2, Y_2 (figure 9 and 10).

Fourier Basis For f_1 , the simulation chooses a smaller number of Fourier basis functions, 5(3) and a higher number for f_2 , 9(7) for the setup with the high(low) signal-to-noise ratio. With the low signal-to-noise ratio, the simulation chooses a smaller number of basis functions, which could be to account for the higher noise in the response variable. The Fourier basis functions perform the best for each setup for the basis expansion regression. Several reasons could contribute to this: First, especially f_1 shows similar curvature order across the domain while the curvature of f_2 , while changing, does not display any eradic jumps. Second, both functions feature periodic behaviour. Third, f_2 does have the same value at the start- and the end of the interval.

A possible explanation applicable for all the specifications might be the effect of the Bias-Variance tradeoff and the following hypothesis: The function f_1 is rather simple. meaning that little bias

is introduced when choosing a small number of basis functions. For f_2 , a higher number of basis functions is needed, resulting from the inherent peculiarities of f_2 . This results in higher numbers of basis functions since the amount of bias is decreasing faster in the number of basis functions than the variance is increasing compared to f_1 .

3.4.2 Functional Principal Component Regression

The model which is used for the FPCR is described in **Estimation using Functional Principal Components**. Additionally to the selection of the truncation parameter K , the choice of the number of FPC's adds to the complexity of the model since the eigenvalues and -functions from the decomposition are influenced by the choice of K that was used to approximate the function. But since the FPCR is ultimately estimated with a linear model with the FPC's as regressors, the degree of freedom of these models is not affected by K , but only by the number of FPC's $n_{FPC} \in \{2, 3, 4\}$.

Monomial Basis For f_1 , the cross-validated MSE is decreasing in the increasing number of FPC's and chosen basis functions for both the setup with the high, and the low signal-to-noise ratio (4,5,6 basis functions for $n_{FPC} \in \{2, 3, 4\}$). In the setup using f_2 we also observe a decreasing MSE in the number of FPC, but a different behaviour of the chosen basis functions: While the model selects 10 basis functions for f_2, Y_1 and f_2, Y_2 using 2 FPC, it only selects 6 for the same two specifications using 3 FPC and 8 for f_2, Y_1 and f_2, Y_2 with 4 FPC. This might be surprising, since one might assume that the number of basis functions is increasing in n_{FPC} since more basis functions led to less smoothing and therefore more variability in the expanded curves that might be exploited by the FPC's. The monomial basis shows the weakest performance for all three basis functions in each setting.

B-spline Basis For f_1, Y_1 , the CV suggests a better model with a higher number of FPC's. While the number of basis functions stays at five for two and three used FPC, it increases to six basis functions for $n_{harm} = 4$. In f_1, Y_1 , the cross-validated MSE is only slightly affected by n_{FPC} , but lowest for $n_{FPC} = 3$, indicating the possibility of over-fitting for $n_{FPC} = 4$. f_2, Y_1 shows a decrease of MSE in increasing n_{FPC} . The same holds true in the setup with f_2 and the high signal-to-noise ratio with the decrease being similar in absolute terms. Similar to the two setups with f_1 , the cross-validated number of basis functions for f_2 is increasing in the number of FPC's (4,6,8 for $n_{FPC} \in \{2, 3, 4\}$)

Fourier Basis We observe similar behaviour as for the FPCR using B-splines. In f_1, Y_1 , the MSE is decreasing in n_{FPC} while the results in f_1, Y_2 might indicate overfitting when using four FPC's. Since it is not possible to calculate the cross-validated MSE for three basis functions for $n_{FPC} = 4$, the increasing number of basis functions as seen in the FPCR with B-splines can not be observed here for sure. f_2, Y_1 displays the greatest relative decline of MSE in the increasing number of FPC's, but in absolute values, therefore acknowledging the higher noise responses for f_2, Y_2 , the decline of MSE is similar to the decline observed for f_2, Y_2 . Both configurations of f_2 are using 5,15,7 basis functions for $n_{FPC} \in \{2, 3, 4\}$: This behaviour in increasing n_{FPC} opposes the previously reported behaviour of the monomial basis and the increasing nature of the B-splines basis functions.

3.4.3 Interpretation and Relevance for Application

Address problem of monomials again – (This could be solved using orthogonal polynomials like Legendre polynomials, see Dattoli, Ricci, and Cesarano 2001)

Address numerical instability?

maybe both in paragraph under results instead of here?

4 Application

The application uses the methods and insights from the previous sections to predict the octane ratings of the introduced gasoline dataset. Although the simulation study granted valuable insights in the different methods in four different settings, it is not enough to determine the method and choice of basis of the application, since there is too much uncertainty involved. To point out some sources of uncertainty: First, opposing to the simulation setup, we do not know the true coefficient function. The insights from just two functions, f_1 and f_2 , is not enough to draw any conclusion. Second, we have no information about the signal-to-noise ratios of the measured octane numbers. Third, we made assumptions about the distribution of ξ that are not relateable to this real-life application where we not know this distribution, neither can we infer something about it. Therefore, we will run all specification again for the gasoline dataset and use the results of the simulation study towards the reading of the results. The application is designed similar to the simulation study: The 60 spectra of the gasoline dataset will be used to regress them on the reported octane numbers and evaluate the results as prediction MSE using 12 fold cross-validation with 5 elements per fold. In total, we conducted 1000 repetitions for each setting.

4.1 Interpretation of Results

4.1.1 Basis Expansion Regression

4.1.2 Functional Principal Component Regression

5 Outlook

5.1 Limitations

Insights from Simulation cannot be Extended to More General Functions

Collinearity Problems in Basis Expansion Regression

Low Number of Basis Functions in FPCR Regression

5.2 Possible Extensions

Orthogonal Polynomials to Solve Collinearity Problems of Monomial Basis

Comparison to Penalty Based Smoothing Procedures

Larger Range for the Number of Basis Functions for FPCR

Larger Range for the Number of Principal Components

Input from Physics Analysis

6 Appendix

6.1 Near-infrared (NIR) Spectroscopy

NIR- spectroscopy is a spectroscopic method that uses the near-infrared region of the electromagnetic spectrum (From 780 nm to 2500 nm). It, therefore, measures the absorption and interaction of this spectrum of radiation with the sample. NIR-spectroscopy is not only faster and cheaper than the standard test procedure – another significant advantage is that it does not need a reagent and thus does not destroy the sample. It is used for analysis in different sectors and fields, like the agrochemical industry and healthcare. Its non-invasive nature makes it also an asset for medical applications like the monitoring of diabetes in which NIR-spectroscopy can detect the worsening of the blood glucose metabolic dysfunction (cf . Li et al. 2020).

In the context of this paper, the gasoline dataset which is used for the simulation and the application is constructed using NIR spectroscopy. According to Gy. Bohács, Z. Ovádi, A. Salgó 1998 NIR-spectroscopy is a feasible method for the analysis of gasoline since most of the absorption that is observed within the described interval of wavelengths is due to overtones and interactions of the radiation with chemical combinations (carbon–hydrogen, carbon–carbon, carbon–oxygen, carbonyl associated groups, aromatic stretching, and deformation vibration of the hydrocarbon molecules). While this paper focuses on the prediction of the octane number of gasoline, other research focuses on different properties of gasoline such as the olefin, naphthaenic and aromatic content (Parisi et al. 1990, as cited in Gy. Bohács, Z. Ovádi, A. Salgó 1998) or the distillation characteristics (Pauls 1985, as cited in Gy. Bohács, Z. Ovádi, A. Salgó 1998)

7 Definition and Proofs

Alexanderian 2015 was referred for the following definitions and proofs.

7.1 Definition (Hilbert-Schmidt Operator)

Given a bounded domain $\mathcal{A} \subset \mathbb{R}^n$, we call a function $c : \mathcal{A} \times \mathcal{A} \rightarrow \mathbb{R}$ a Hilbert-Schmidt kernel if

$$\int_{\mathcal{A}} \int_{\mathcal{A}} |c(x, y)|^2 dx dy < \infty \quad (54)$$

where $c \in \mathbb{L}^2(\mathcal{A} \times \mathcal{A})$. Let K be an integral operator on $\mathbb{L}^2(\mathcal{A})$ such that $K : \nu \rightarrow K\nu$ for $\nu \in \mathbb{L}^2(\mathcal{A})$, by

$$[K\nu](x) = \int_{\mathcal{A}} c(x, y) \nu(y) dy \quad (55)$$

When an integral operator K is linear and bounded, it is called a Hilbert-Schmidt operator. The linearity of the operator K is simply proved. Additionally assume that $\alpha, \beta \in \mathbb{R}$ and $\theta \in \mathbb{L}^2(\mathcal{A})$.

$$\begin{aligned} [K(\alpha\nu + \beta\theta)](x) &= \int_{\mathcal{A}} c(x, y) (\alpha\nu(y) + \beta\theta(y)) dy \\ &= \int_{\mathcal{A}} c(x, y) \alpha\nu(y) dy + \int_{\mathcal{A}} c(x, y) \beta\theta(y) dy \\ &= \alpha \int_{\mathcal{A}} c(x, y) \nu(y) dy + \beta \int_{\mathcal{A}} c(x, y) \theta(y) dy \\ &= \alpha[K\nu](x) + \beta[K\theta](x) \end{aligned} \quad (56)$$

For boundedness of the oprator K ,

$$\begin{aligned} \|K\nu\|_{\mathbb{L}^2(\mathcal{A})}^2 &= \int_{\mathcal{A}} \left| [K\nu](x) \right|^2 dx \\ &= \int_{\mathcal{A}} \left| \int_{\mathcal{A}} c(x, y) \nu(y) dy \right|^2 dx \\ &\leq \int_{\mathcal{A}} \left(\int_{\mathcal{A}} |c(x, y)|^2 dy \right) \left(\int_{\mathcal{A}} |\nu(y)|^2 dy \right) dx \quad (\text{Cauchy-Schwarz}) \\ &= \|c\|_{\mathbb{L}^2(\mathcal{A} \times \mathcal{A})} \|\nu\|_{\mathbb{L}^2} < \infty \end{aligned} \quad (57)$$

7.2 Lemma

The curves $X(t) \in \mathbb{L}^2[0, 1]$ is expanded by the eigenfunctions $\{\nu^m\}$ as Equation 19. The coefficients ξ^m corresponding to eigenfunctions ν^m satisfy the following properties:

1. $\mathbb{E} [\xi^m(\omega)] = 0$
2. $Cov(\xi^m(\omega), \xi^n(\omega)) = \delta^{m,n} \lambda^m$
3. $Var(\xi^m(\omega)) = \lambda^m$

Remind that $\delta^{m,n} = 0$ if $m \neq n$, otherwise 1.

Proof. Assume that $F(t)$ is the centered process of $X(t)$, namely, $F(t) = X(t) - \int_{\Omega} X(t) dP(\omega)$. To obtain the first result, we can show that

$$\begin{aligned}
\mathbb{E}[\xi^m] &= \mathbb{E} \left[\int_0^1 F(t) \nu_j(t) dt \right] \\
&= \int_{\Omega} \int_0^1 F(t) \nu^m(t) dt dP(\omega) \\
&= \int_0^1 \int_{\Omega} F(t) \nu^m(t) dP(\omega) dt \quad (\text{Fubini}) \\
&= \int_0^1 \int_{\Omega} F(t) dP(\omega) \nu^m(t) dt \\
&= \int_0^1 \mathbb{E}[F(t)] \nu^m(t) dt = 0
\end{aligned} \tag{58}$$

where $\mathbb{E}[F(t)]$ is 0 since $F(t)$ is a centered process. The second claim is proved as:

$$\begin{aligned}
\mathbb{E}[\xi^m \xi^n] &= \mathbb{E} \left[\int_0^1 F(s) \nu^m(s) ds \int_0^1 F(t) \nu^n(t) dt \right] \\
&= \mathbb{E} \left[\int_0^1 \int_0^1 F(s) \nu^m(s) F(t) \nu^n(t) ds dt \right] \quad (\text{Fubini}) \\
&= \int_0^1 \int_0^1 \mathbb{E}[F(s) F(t)] \nu^m(s) \nu^n(t) ds dt \\
&= \int_0^1 \left(\int_0^1 c(s, t) \nu^m(s) ds \right) \nu^n(t) dt \\
&= \int_0^1 [K \nu^m](t) \nu^n(t) dt \\
&= \langle K \nu^m, \nu^n \rangle \\
&= \langle \lambda^m \nu^m, \nu^n \rangle = \delta^{m,n} \lambda^m
\end{aligned} \tag{59}$$

where $\delta^{m,n} = 1$ if $m = n$, otherwise 0. The result is produced from orthonormality of the eigenfunctions.

$$Cov(\xi^m, \xi^n) = \mathbb{E}[\xi^m \xi^n] - \mathbb{E}[\xi^m] \mathbb{E}[\xi^n] = \delta^{m,n} \lambda^m \tag{60}$$

where $\mathbb{E}[\xi^m] = \mathbb{E}[\xi^n] = 0$ as the first property. The last assertion is confirmed from the above two properties.

$$Var[\xi^m] = \mathbb{E}[(\xi^m - \mathbb{E}[\xi^m])^2] = \mathbb{E}[(\xi^m)^2] = \lambda^m \tag{61}$$

The original process $X(t)$ also has the same properties as the centered one since

$$X(t) = F(t) + \mathbb{E}[X(t)] = \mu(t) + \sum_{m=1}^{\infty} \xi^m \nu^m(t) \tag{62}$$

□

7.3 Theorem (Karhunen-Loève expansion)

Let $X : [0, 1] \rightarrow \mathbb{R}$ be a mean-square continuous stochastic process, namely, $\lim_{\epsilon \rightarrow 0} \mathbb{E}[(X(t+\epsilon) - X(t))^2] = 0$, such that $X \in \mathbb{L}^2[0, 1]$. Then there exists a basis ξ^m of $\mathbb{L}^2[0, 1]$ such that for all $t \in [0, 1]$,

$$X(t) = \mu(t) + \sum_{m=1}^{\infty} \xi^m \nu^m(t), \quad (63)$$

where $\mu(t)$ is the mean function of $X(t)$ and coefficients ξ^m are given by $\int_0^1 (X(t) - \mu(t)) \nu^m(t) dt$. These coefficients satisfy the following conditions.

1. $\mathbb{E}[\xi^m(\omega)] = 0$
2. $Cov(\xi^m(\omega), \xi^n(\omega)) = \delta^{m,n} \lambda^m$
3. $Var(\xi^m(\omega)) = \lambda^m$

Proof. Let K be a Hilbert-Schmidt operator as in Equation 18. We know that K has a complete set of eigenfunctions ν^m in $\mathbb{L}^2[0, 1]$ and non-negative eigenvalues λ^m since K is a positive compact self-adjoint operator. With the reminder that ξ^m satisfy the three conclusions by Lemma 7.2, we prove this expansion by considering

$$\epsilon_N(t) := \mathbb{E} \left[\left(X(t) - \mu(t) - \sum_{m=1}^N \xi^m \nu^m(t) \right)^2 \right] = \mathbb{E} \left[\left(F(t) - \sum_{m=1}^N \xi^m \nu^m(t) \right)^2 \right] \quad (64)$$

where $F(t)$ is the centered process of $X(t)$. Once it is shown that $\lim_{N \rightarrow \infty} \epsilon_N(t) = 0$ uniformly in $[0, 1]$, the proof is completed.

$$\begin{aligned} \epsilon_N(t) &= \mathbb{E} \left[\left(F(t) - \sum_{m=1}^N \xi^m \nu^m(t) \right)^2 \right] \\ &= \mathbb{E}[F(t)^2] - 2\mathbb{E} \left[F(t) \sum_{m=1}^N \xi^m \nu^m(t) \right] + \mathbb{E} \left[\sum_{m=1}^N \sum_{n=1}^N \xi^m \xi^n \nu^m(t) \nu^n(t) \right] \end{aligned} \quad (65)$$

Here, $\mathbb{E}[F(t)^2] = c(t, t)$ as in Equation 17 since $F(t)$ is the centered process. Now, take the second term

$$\begin{aligned} \mathbb{E} \left[F(t) \sum_{m=1}^N \xi^m \nu^m(t) \right] &= \mathbb{E} \left[F(t) \sum_{m=1}^N \left(\int_0^1 F(s) \nu^m(s) ds \right) \nu^m(t) \right] \\ &= \mathbb{E} \left[\sum_{m=1}^N \left(\int_0^1 F(t) F(s) \nu^m(s) ds \right) \nu^m(t) \right] \\ &= \sum_{m=1}^N \left(\int_0^1 \mathbb{E}[F(t) F(s)] \nu^m(s) ds \right) \nu^m(t) \\ &= \sum_{m=1}^N \left(\int_0^1 c(t, s) \nu^m(s) ds \right) \nu^m(t) \\ &= \sum_{m=1}^N [K \nu^m](t) \nu^m(t) \\ &= \sum_{m=1}^N \lambda^m \nu^m(t) \nu^m(t) = \sum_{m=1}^N \lambda^m \nu^m(t)^2 \end{aligned} \quad (66)$$

where the covariance function $c(t, s)$ has the Hilbert-Schmidt operator as in Equation 18. It turns out the product of the eigenfunction and the corresponding eigenvalue. For the last term, we derive from Equation 59 that

$$\begin{aligned}
\mathbb{E} \left[\sum_{m=1}^N \sum_{n=1}^N \xi^m \xi^n \nu^m(t) \nu^n(t) \right] &= \sum_{m=1}^N \sum_{n=1}^N \mathbb{E}[\xi^m \xi^n] \nu^m(t) \nu^n(t) \\
&= \sum_{m=1}^N \sum_{n=1}^N \delta^{m,n} \lambda^m \nu^m(t) \nu^n(t) = \sum_{m=1}^N \lambda^m \nu^m(t)^2
\end{aligned} \tag{67}$$

where $\delta_{m,n} = 1$ if $m = n$, otherwise 0. Therefore, by Equations 65, 66, and 67 we obtain

$$\epsilon_N(t) = c(t, t) - \sum_{m=1}^N \lambda^m \nu^m(t) \nu^m(t) \tag{68}$$

implementing Mercer's Theorem this proof is concluded by

$$\lim_{N \rightarrow \infty} \epsilon_N(t) = \lim_{n \rightarrow \infty} \mathbb{E} \left[\left(F(t) - \sum_{m=1}^N \xi^m \nu^m(t) \right)^2 \right] = 0 \tag{69}$$
